Adolescent Health 3

Worldwide application of prevention science in adolescent health

Richard F Catalano, Abigail A Fagan, Loretta E Gavin, Mark T Greenberg, Charles E Invin Jr, David A Ross, Daniel T L Shek

The burden of morbidity and mortality from non-communicable disease has risen worldwide and is accelerating in low-income and middle-income countries, whereas the burden from infectious diseases has declined. Since this transition, the prevention of non-communicable disease as well as communicable disease causes of adolescent mortality has risen in importance. Problem behaviours that increase the short-term or long-term likelihood of morbidity and mortality, including alcohol, tobacco, and other drug misuse, mental health problems, unsafe sex, risky and unsafe driving, and violence are largely preventable. In the past 30 years new discoveries have led to prevention science being established as a discipline designed to mitigate these problem behaviours. Longitudinal studies have provided an understanding of risk and protective factors across the life course for many of these problem behaviours. Risks cluster across development to produce early accumulation of risk in childhood and more pervasive risk in adolescence. This understanding has led to the construction of developmentally appropriate prevention policies and programmes that have shown short-term and long-term reductions in these adolescent problem behaviours. We describe the principles of prevention science, provide examples of efficacious preventive interventions, describe challenges and potential solutions to take efficacious prevention policies and programmes to scale, and conclude with recommendations to reduce the burden of adolescent mortality and morbidity worldwide through preventive intervention.

Introduction

Despite some regional differences and a concentration of deaths in low-income and middle-income countries, there is commonality in the causes of adolescent deaths worldwide.1 The causes of adolescent death include communicable diseases (HIV/AIDS, tuberculosis, and lower respiratory-tract infection) and non-communicable diseases related to problem behaviours (motor vehicle fatalities, violence, self-harm, alcohol, tobacco, and other drugs, and risky sex leading to early or unintended pregnancy). Further, adolescence, partitioned into early (11–13 years), middle (14–18 years), and late (19–24 years) by the American Academy of Child and Adolescent Psychiatry,2 is a common period for the onset of symptoms and behaviours that lead to disorders in adulthood. For some disorders (eg, alcohol misuse and dependence, antisocial personality disorder), greater than 50% of first diagnoses across the life course are by age 25 years.1 Preventing adolescent problem behaviours might reduce the burden of morbidity in adolescence and adulthood.

Primary approaches to ameliorate these behaviour problems are health promotion, prevention, and treatment.1 At the turn of the 20th century in high-income countries, adolescence became a distinct time of life because of industrialisation, advances in medicine, improved nutrition, and public health, which increased the need for an educated workforce and led to universal education through the second decade of life.4 This extended period of dependence coincided with a rise in adolescent problem behaviours. Programmes designed to prevent these problem behaviours were first developed in the late 1960s in high-income countries, although few of these interventions were effective.5–7 In response to the disappointing results, prevention programme developers aligned with the science of behaviour development that discovered predictors. A second generation of prevention efforts sought to use this information to design programmes to address these predictors of specific

Key messages

• Behaviour problems are important causes of adolescent morbidity and mortality
• There is sufficient evidence from controlled trials that carefully designed preventive interventions can improve adolescent health
• Effective adolescent health programmes should include a combination of preventive policies and programmes before and during the second decade of life
• A programme of public education is needed to ensure that policy makers, practitioners, scientists, and the general public are made aware of the health and social benefits and cost savings from evidence-based preventive interventions
• Research is needed on how to most effectively take such evidence-based prevention interventions to scale, including research on how to build community capacity, identify local need, match need to efficacious prevention interventions, support and sustain these interventions, and learn what adaptations might be needed for programmes designed in high-income countries to be effective in low-income and middle-income countries
• An international agency such as WHO, UNICEF, or The World Bank should be encouraged to convene a guideline development group to identify broad behavioural health risks confronting adolescents, recommend preventive policies and programmes that have evidence of reducing these risks and promoting adolescent health, and advise on actions that countries should institute to take up and sustain a national programme to promote adolescent health
• Databases should be developed, including a database of community surveys that comprehensively measure structural and intermediate determinants and health and behaviour problems, and a database of efficacious preventive policies and programmes across behaviour problems and health outcomes, the structural and intermediate determinants they address, and their target populations
problem behaviours, which was more successful.3,25 These prevention interventions focusing on single problems came under criticism, and there was a movement towards considering the co-occurrence of problem behaviours within the adolescent and understanding the overlap in predictors across many behaviours.26 Others—ie, prevention practitioners, policy makers, and prevention scientists—advocated for more focus on factors that promote positive youth development, in addition to the focus on reducing factors that predict problems.27 They called for understanding the developmental processes involved in these disorders, including structural, intermediate, and individual risk and protective factors. Such concerns helped expand the design of prevention programmes to include components aimed at health promotion.12 Over the past 30 years, several controlled trials have shown that preventive and promotive policies and programmes (called preventive interventions hereafter) can be efficacious and cost effective at reducing adolescent problem behaviour and improving health.11,12 Prevention science has had a different history in low-income and middle-income countries. In these countries, economic conditions have somewhat delayed the recognition of adolescence as a distinct life stage, although as these countries develop economically, with population shifts to urban centres, there is a growing recognition of adolescence.14 The research base that was developed in high-income countries has recently begun to be applied to low-income and middle-income countries through translation of existing approaches and developing and testing new preventive interventions in these lower-income contexts.

Treatment of adolescent behaviour problems remains the most common approach worldwide.15 Ultimately, some combination of treatment and prevention programmes would be ideal, but how to achieve this vision is somewhat uncertain.26 Investigators suggest that reducing a small amount of risk in the general (and proportionally larger) population might be epidemiologically more beneficial than reducing larger amounts of risk in the smaller, high-risk, segment of society.26 Although evidence-based treatments are important, we advocate applying the growing research base for prevention science worldwide to substantially reduce morbidity and mortality.27

We provide an overview of the research base for prevention science and illustrative evidence of the efficacy of various preventive interventions. We surveyed broad outcomes, including obesity, violence, mental health, substance misuse, traffic crashes, pregnancy, and sexually transmitted infections, by assessing recent reviews and doing targeted searches of prevention controlled trials. We take a purposive approach, and have chosen to illustrate what works in prevention and health promotion, and to refer to other more comprehensive and systematic reviews for other efficacious and non- efficacious interventions. In our opinion, the preventive interventions we have selected provide a broader overview of what is possible in preventing adolescent problems than comprehensive reviews of prevention programmes of a certain type or targeting a single problem behaviour.

We selected the programmes and policies identified in this report because they were tested in randomised or quasi-experimental trials, had a sustained and statistically significant effect on problem behaviours during adolescence at least 1 year after intervention, operate at different points in development during childhood and adolescence, and address accumulation of risk28 as well as adolescent risk onset.28 We chose these examples to provide some diversity in worldwide context, although most testing, particularly the long-term investigation of outcomes, has been done in high-income countries.

The science of prevention

In the past three decades, prevention science has emerged as a discipline built on the integration of life-course development research, community epidemiology, and preventive intervention trials.22 Prevention science is based on a framework that identifies empirically verifiable precursors that affect the likelihood of undesired health outcomes. Precursors include structural, intermediate (family, school, peer), and individual risk factors that predict an increased likelihood of problems, and protective factors that mediate or moderate exposure to risk or directly decrease the likelihood of problems.1,2,25 Risk and protective factors emerge at particular periods of development. Some factors are problem specific and some are more general, predicting multiple outcomes, including alcohol, tobacco, and other drug misuse, adolescent pregnancy, violence, delinquency, school dropout, and mental health disorders.1,22 The commonality in risk factors across problem behaviours means that interventions that address a risk factor will probably affect many problems.25 This commonality also suggests that preventive interventions that address precursors of multiple problems are an efficient approach. Further, exposure to several risk factors, and lack of exposure to protective factors, strengthens the likelihood of problem outcomes, but preventive interventions that effectively reduce risk and enhance protective factors can have the reverse effect and make healthy development more probable (appendix).1,22

Although several typologies for targeting preventive interventions have been described,26 we use the categories of universal, selective, and indicated preventive interventions (appendix). The intended application of universal preventive interventions is across a population irrespective of risk. Policies that address structural determinants are often applied universally, as are programmes that encourage all young people to adopt skills to refuse offers of alcohol, tobacco, and other drugs. Selective preventive interventions are applied to groups with raised risk for poor outcomes—eg, programmes targeted at low-income neighbourhoods or families. Indicated preventive interventions are applied to individuals who are already showing symptoms of a disorder.
or problem behaviour—eg, working with young people after their first contact with the justice system to prevent further penetration into the system. The policies and programmes we include provide examples of all three prevention approaches.

Risks tend to cluster in two patterns across childhood and adolescence, a so-called early accumulated risk cluster and a so-called adolescent-onset risk cluster. Risks accumulate early in the life course when developmental challenges are not met and problems begin to cascade, so that having one risk makes it more probable that the individual will develop another.26 For example, early family adversity and risks, such as low income and poor family management including abuse and neglect, make it harder for children to be ready for school, hindering their academic achievement. These children might best be helped by selective interventions implemented in the early years to counteract family risk and avoid school-related problems. If early developmental challenges are not met, risk can continue to accumulate in adolescence, with low school achievement leading to rejection by prosocial peers, increased interaction with deviant peers, and the start of problem behaviours.27 These adolescents might best be helped by indicated preventive intervention provided to those showing signs and symptoms of problems. The adolescent-onset pattern24 of risk arises in early to late adolescence. In the absence of protective influences, post-pubertal normative increases in problem behaviours can be exacerbated through negative peer influences. This pattern can affect all adolescents, even those without accumulated early risk, and might be targeted through preventive universal interventions with parents, schools, or communities that seek to reduce favourable attitudes towards problem behaviours and increase protection.28

Several preventive interventions have been tested in controlled trials and shown to be efficacious.14–12

**Evidence of efficacy**

Table 1 and the appendix show how the efficacious interventions target structural, intermediate, and individual risk, divided into childhood, early adolescence, and late adolescence. We summarise the types of prevention interventions that address structural risk through policy changes and those that address intermediate risks in the family, school, peer, and individual. Table 2 details these programmes and policies, where and how they have been assessed, and the effect size, odds ratio, or change in prevalence; we also show the risk cluster addressed (early accumulated or adolescent-onset risk) and the intervention target (universal, selective, and indicated).

Prevention policies that address structural risk factors have the potential to affect whole populations and can be implemented broadly, from local administrative districts to entire nations. Policies in table 2 were tested in Australia, Canada, the UK, and the USA. The example efficacious policies include providing minors (ie, those younger than 18 years) with free or easier access to contraception, raising taxes on alcohol, increasing the minimum legal drinking age, and having graduated licensing policies for adolescent drivers (eg, restrictions on when and under what conditions they are allowed to drive). Assessments of these types of policies have shown reductions in unintended adolescent pregnancy and risky sexual behaviour, harmful drinking, traffic crashes, and crime.

Preventive programmes that address family and individual risk factors have shown effects across development in trials done in the USA. For example, the Nurse-Family Partnership46 provided services to low-income, first-time mothers to improve their health and behaviour while pregnant and strengthen parenting skills when children were infants. All other interventions targeted both parents and children to simultaneously enhance protection and reduce family and individual risks. Examples include enhanced education services for primarily low-income, very young children to improve their cognitive, language, and social-cognitive skills,46–50 and interventions that strengthen parenting skills, parent–child communication, and affective relationships. These include universal (eg, the Strengthening Families Program for Parents and Youth 10–14257,258) and the Computer-Based Intervention54,55), selective (eg, the New Beginnings Program56), and indicated programmes (eg, Functional Family Therapy57). Across programmes, significant effects were identified in early childhood to late adolescence and include reduced child abuse and neglect, alcohol and other drug misuse, risky sexual activity, depression, and delinquency and crime, and greater educational attainment.

Preventive programmes that address school and individual risk factors include many primary and secondary school programmes. The examples in table 2 were assessed

The full version of this table is in the appendix. ES=effect size. OR=odds ratio. K-kindergarten, generally before year 1. *Grade refers to year in school.

In Australia, Kenya, Malawi, and the USA. Two of these programmes (the Seattle Social Development Project66-68 and the Gatehouse Project61,62) include classroom-based curricula taught by teachers to improve student cognitive, social, and emotional competencies and seek to alter school factors by enhancing teacher instructional and student classroom management skills or changing school and classroom norms for behaviour. Another efficacious prevention programme provides cash incentives for students to remain in school. Together, these school-based prevention programmes have shown effects in reducing aggression, crime, alcohol and tobacco use, unwanted pregnancies, sexually transmitted diseases, and mental health symptoms and disorders, and have shown increases in secondary school completion, educational attainment, and income. Positive outcomes have been...
shown across adolescence, with enduring effects 1–15 years after intervention.

The last set of efficacious prevention programmes shown in Table 2 addresses peer and individual risk factors and seek to change many outcomes, including drug use (Unplugged65 and Life Skills Training66,67), positive development (Positive Adolescent Training Through Holistic Social Programs68,69), and risky sexual behaviours (Stepping Stones70 and Sistering, Informing, Healing, Loving and Empowering71). These prevention programmes have been assessed in several European countries, Hong Kong, South Africa, and the USA; they provide services directly to young people and target adolescent-onset risk factors. Sessions seek to promote positive peer relationships, interpersonal skills, and skills to counteract negative peer influences. Effective interventions also simultaneously promote the development of individual skills and competencies via group-based sessions in school classrooms or community settings. Across interventions, positive effects have included reduced alcohol and other substance misuse, delinquency, risky sexual activity, sexually transmitted disease (herpes simplex virus), unwanted pregnancy, and academic failure, and increased psychosocial competencies.

The programmes and policies described are examples of prevention interventions that have shown significant reductions in problem behaviours in children and adolescents by targeting relevant risk and protective factors from infancy to adolescence. These illustrative interventions have worked in many contexts, from policy to the individual. Furthermore, they have used many formats, including laws, in-person delivery, and electronic media. Although there is variation in their effect sizes and ability to produce desired changes in the long term, these strategies affect various problem behaviours associated with adolescent morbidity and mortality. Our approach is illustrative, and there are many more prevention interventions that are efficacious. Employing a combination of programmes and policies that engage schools, families, and communities will probably yield long-term beneficial effects.3,72 Early intervention might be best to forestall the accumulation of risk, but investments are also needed during adolescence to offset the pattern of adolescent-onset risk and to work with those whose accumulated risk now needs indicated prevention.

The efficacy of many preventive interventions has been established and provides a strong foundation for action. However, several key gaps in our knowledge remain. Most preventive interventions have been assessed in high-income countries, and less prevention research has been done in low-income and middle-income countries. Across nations, there has been a lack of controlled trials that assess long-term outcomes or study the comparative efficacy of prevention strategies. Further, although many prevention programmes have been efficacious, few replications have been undertaken, and effectiveness trials are uncommon. Funding for prevention trials has favoured innovation and efficacy rather than replication. To ensure that the discipline develops robust interventions, advocacy for research funding targeting replication, generalisation, and effectiveness trials is needed.

In the USA, the Washington State Institute for Public Policy has advanced preventive science by estimating the cost-effectiveness of diverse prevention programmes with scientifically rigorous standards applied consistently across programmes. Six of the interventions we include have been assessed by the Institute, and all have shown economic benefits. Benefit-per-dollar cost ratios range from US$2.11 to US$42.13, and savings per participant range from $1348 to $31036.13 However, cost–benefit estimates of interventions are scarce, due to challenges in calculating accurate intervention effect sizes; the failure of many programme developers to fully document and make available intervention costs; complexities in doing economic analyses (eg, establishing appropriate discount rates, making assumptions regarding future events, and lifetime benefits etc); and few incentives for researchers to undertake such work. Existing cost–benefit studies differ in their methods.1 Reaching consensus on standards for undertaking cost–benefit analyses and making this a routine part of programme assessment can help policy makers choose models that not only improve adolescent health, but also ensure that investments return downstream benefits.1,78,79

Although gaps remain in the development and assessment of preventive interventions and policies, existing models offer promise for reducing the substantial public health burden. Widespread dissemination would provide opportunity to undertake replication, generalisation, and effectiveness trials to ensure that we fill knowledge gaps.

**Translation of efficacious interventions**

A key challenge for prevention science is translating scientific advances into practice, with the goal of supporting the dissemination and sustainability of evidence-based interventions at scale within and across nations.86 Improved translation of efficacious prevention programmes to standard practice is needed not only in low-income and middle-income countries, but also in high-income countries. For example, a national study of public secondary schools in the USA87 showed that only about 43% of schools implement efficacious drug-prevention curricula. Substantial barriers that hinder the widespread dissemination of prevention interventions in countries of all incomes include restricted government financing of preventive interventions, lack of prevention training in professional communities, and restricted knowledge of, or support for, prevention in the general public.87,88

Many government officials lack training in public health89 and often focus policies and funding on remedial rather than preventive efforts. Further, there is unbalanced attention focused on physical health problems and medical treatment at the expense of mental health problems and
psychosocial intervention. The consequence is that financial resources spent on prevention are usually inadequate, and prevention programming is done in an unsystematic and piecemeal manner. Improving the technical capacity of government, fostering trust between government and researchers, and establishing the standard of using scientific evidence to inform decisions are crucial directions for the future.

Professionals working with young people in countries of all incomes usually lack training in prevention and evidence-based practice, resulting in diminished appreciation for prevention and outcome assessment. Poor communication and dissemination of research findings about prevention research and health-policy analysis hinder the use of research findings in prevention practice. Overcoming these barriers might be helped by user-friendly packaging of research findings; increased dialogue between policy makers, researchers, and professionals and practitioners; and the provision of incentives for researchers to work towards these goals and incentives for practitioners to use the results in their programming.

Similarly, the general public does not advocate for the use of effective prevention strategies. Although the public often has knowledge of and a high expectation for the efficacy of preventive medical interventions such as vaccines, they have little knowledge of the efficacy of psychosocial preventive initiatives. To overcome this lack of awareness, there is a need for broad dissemination of information on prevention, its efficacy, and the ability of preventive interventions to save money as well as lives.

Some barriers to the dissemination of evidence-based prevention interventions are more prevalent in low-income and middle-income countries than high-income countries. In low-income and middle-income countries, adolescence might not be fully acknowledged as an important life stage, and thus, interventions that focus on adolescents might receive little support. Further, there might be perceptions that efficacious preventive interventions developed in high-income countries might not be acceptable or applicable in lower income settings, in view of the important differences in the epidemiologic patterns, social norms and traditional practices, and levels of poverty in these countries.

There is a need to expand research on adolescent preventive interventions in low-income and middle-income countries so that context-specific issues can be addressed. However, a growing body of research shows that some interventions created in high-income countries can be translated to and be effective in low-income and middle-income countries. For example, a review of 83 sex education programmes based on western theories of behaviour change showed that two-thirds were effective at reducing adolescent sexual risk behaviour in several countries, cultures, and groups of young people. The studies included nine from high-income countries other than the USA and 18 from low-income and middle-income countries.

Although these examples show that effective interventions can be successfully replicated in different contexts, there is substantial debate on how to transfer programmes to new settings, both within and across nations. Advocates of strict implementation fidelity highlight evidence that participant outcomes are stronger and sometimes only achieved when interventions are replicated as closely as possible to their original protocol. Others contend that adaptations are needed to ensure that an intervention’s content, language, examples, and methods of delivery are culturally appropriate and relevant to the new population. This view anticipates that modifications will increase participant responsiveness, programme effectiveness, and sustainability.

The goal is to have enough effective interventions available worldwide so that adopters can select those that closely match their own population, needs, and resources, then faithfully replicate them. Until that is possible, dissemination efforts can be fostered by better identification of the core elements of efficacious interventions—the content, activities, and modes of delivery that best represent their underlying logic and causal mechanisms. Adopters must be aware of these principles and ensure their full implementation. When planned adaptations of programme features substantially revise the intervention, rigorous assessment, perhaps comparing the unaltered intervention to the adaptation, should be done to ensure that the new version is effective. Innovative and cost-effective methods for designing and assessing programme adaptations are emerging in prevention science to guide this process.

Building capacity

Dissemination of efficacious prevention interventions across diverse nations and communities begins with efforts to identify the most salient needs. Although there are similarities across nations in the leading causes of adolescent mortality, there are also differences. Such differences also exist within nations, at the community level. Selecting the right intervention for the right population requires the identification and prioritisation of community need. Community monitoring systems that assess behaviour problems, as well as risk and protective factors, can help communities target prevention strategies. The Communities That Care (CTC) Youth Survey is one example of a valid, reliable, and efficient school survey method that can be used to identify local levels of risk and protective factors as well as alcohol, tobacco, and other drug misuse, delinquency, violence, and depression. This survey has been used in Australia, India, Netherlands, the UK, and the USA. The survey assesses community need for prevention by providing information on risk, protection, and youth outcomes that are most elevated, and thus most appropriate for prevention efforts. When surveys are repeated over time, communities can monitor the effects of prevention policies and programmes.
Other assessment methods include the Monitoring the Future survey in the USA and The European School Survey Project on Alcohol and Other Drugs, which focus on assessing adolescent drug misuse. The school-based Global Student Health Survey assesses nine problem behaviours and some predictors in young people aged 13–15 years. The Early Development Index, administered widely in Australia, Canada, and other countries, monitors physical health and wellbeing of young children entering school, and measures some risk and protective factors (including social competence, emotional maturity, language and cognitive development, and communication skills). Despite these worthy examples, additional surveys are needed that can measure risk and protective factors and problem behaviours comprehensively at a local level. Greater infrastructure development to support use of monitoring systems is also needed in all countries, but promising developments have been made towards this goal by WHO (eg, Child and Adolescent Health Survey), the World Bank (eg, Living Standards Measurement Study), European School Survey Project on Alcohol and Other Drugs, and others. The development of a database of these instruments, which lists constructs measured and scales, would allow adoption of measures for community monitoring systems.

Once local levels of risk, protection, and behavioural outcomes are identified and prioritised, the most efficacious prevention approaches that meet these needs can be chosen and implemented. A challenge at this stage is for communities to ensure that the programme elements crucial to success have been well implemented, because careful implementation of programmes’ core components has been associated with stronger effects on targeted outcomes. There will be challenges to implementation, and communities will need technical assistance to help them monitor the quality of implementation. Communities must ensure that they use methods and delivery systems that reach targeted participants in sufficient numbers to achieve population-level outcomes. Some trials have shown that reaching 40–60% of targeted participants might be sufficient to produce community-level effects.

Methods for increasing the capacity of local communities to undertake successful prevention efforts are only beginning to emerge. Five core components for capacity building have been identified; these include improvement of data collection, defining the epidemiology of the health problem, estimation of the societal cost of the problem, understanding public perceptions of problem causation, and engaging policy makers to improve prevention and control. Strong collaborations between researchers and practitioners are essential to build this capacity. Such partnerships have been the focus of community-based prevention trials in the USA, such as the CTC or the Promoting School Community University Partnerships to Enhance Resilience prevention models. In the CTC model, broad-based community coalitions that include representatives of government, non-governmental organisations, service sectors, and key community leaders receive structured training workshops and proactive technical assistance for assessing their prevention needs, targeting these needs with tested and efficacious prevention strategies, and ensuring that these new strategies are well implemented and integrated with existing prevention efforts. A randomised, controlled assessment has shown that CTC substantially increased the number and scope of prevention services in intervention compared with control communities, and produced community-wide reductions in alcohol and tobacco use and delinquent behaviour that were sustained 2 years later.

As efficacious programmes become more widely adopted across communities and nations, the need for strategies to enhance long-term sustainability are crucial. Research on the conditions that facilitate or undermine the maintenance of new initiatives is beginning to emerge. An assessment of the CTC prevention system in 110 US communities in Pennsylvania estimated a survival rate of CTC coalitions of about 60% over 6 years after withdrawal of state funding, with the primary factors leading to sustainability including local funding and planning for sustainability and fidelity to the CTC model. Other research has suggested that long-term sustainability is associated with strong support for the programme among staff and leaders; widespread belief in the benefits of the innovation; and a strong integration between the new innovation and the agency’s mission statement, schedule of services, and staffing profile.

**Conclusions**

Although there are many significant challenges to going to scale with efficacious prevention interventions, advances have been made. For continued progress, a change in attitude is needed to position the importance of preventive programmes in the minds of parents, communities, professionals, and policy makers. Specific actions might help support widespread adoption of preventive interventions. First, government officials must appreciate the importance of tested, efficacious prevention programmes and policies that have the potential to reduce health spending and other social costs (table 3), and support the development of a widespread prevention

delivery system for adolescents. Few examples of such prevention delivery systems exist at present. Prevention funding needs to move from short-term discretionary grants to stable funding streams. Second, professional training in prevention science is needed. Prevention science and evidence-based practice should be included in the basic and continuing professional education programmes for professionals working with young people. Third, an increase in local community capacity to assess needs is needed to identify priority problems. This increase in capacity should include the development and use of monitoring systems that identify community levels of risk, protection, and behaviour problems in children and adolescents, and improved collaboration between the science and practice community. Constructing a database of community monitoring methods will also help. Fourth, research on adaptation, going to scale, and sustainability of efficacious prevention programmes and policies across countries of all incomes needs to be done. Adaptation research will help ensure that evidence-based prevention interventions can be tailored to other contexts. Since many preventive interventions have been tested in high-income countries, a concerted effort is needed to address barriers to widespread adoption in low-income and middle-income countries. Translational research should be promoted through increased funding, training of translational investigators, removal of barriers blocking collaboration between scientists and practitioners, and development of administrative facilitation for translational research. Fifth, there is a need to create a credible database documenting exemplary and promising prevention interventions across behaviour problems, including, at a minimum, substance misuse, violence, crime, early school leaving, obesity, mental health, unsafe sex, unintended pregnancy, and risky and unsafe driving. Although some databases have programmes that address many outcomes, none covers this breadth of outcomes. Sixth, research is needed to establish whether there are unique risk and protective factors in the low-income and middle-income countries that might provide the basis for additional targets for preventive interventions. Reducing the emergence of problems during adolescence should have a substantial effect on reducing the burden of health problems well into adulthood.
